ABSTRACT

Interactions of the ESCRT complexes are critical for endosomal trafficking. We identify two domains with potential significance for this process. The MABP domain present in metazoan ESCRT-I/MVB12 subunits, Crag, a regulator of protein sorting, and bacterial pore-forming proteins might mediate novel membrane interactions in trafficking. The UBAP1-MVB12-associated UMA domain found in MVB12 and UBAP1 defines a novel adaptor that might recruit diverse targets to ESCRT-I.

1 INTRODUCTION

A key aspect of eukaryotic intracellular trafficking is the sorting of cell-surface proteins into multi-vesicular endosomes or bodies (MVBs), which eventually fuse with the lysosome, where they are degraded by lipases and peptidases. This is the primary mechanism for downregulation of signaling via transmembrane receptors and removal of misfolded or defective membrane proteins (Raiborg and Stenmark, 2009). This process is also utilized by several viruses (e.g. HIV-1) to facilitate budding of their virions from the cell membrane (Morita *et al*., 2007). Studies in animals and fungi have shown that it depends on an intricate series of interactions, which is initiated via ubiquitination (typically one or more mono-ubiquitinations) of the cytoplasmic tails of membrane proteins by specific E3 ligases (d'Azzo *et al*., 2005). Ubiquitinated membrane proteins are then captured into endosomes by the ESCRT system and prevented from being recycled back to the plasma membrane via the retrograde trafficking system. The ESCRT system also folds the endosomal membranes into invaginations that are concentrated in these ubiquitinated targets and catalyzes their abscission into intraluminal vesicles inside the endosome. This largely seals the fate of these membrane proteins as targets for lysosomal degradation. The ESCRT system is comprised of four major protein complexes, ESCRT-0 to ESCRT-III, which are successively involved in the above-described steps (Raiborg and Stenmark, 2009). ESCRT-0, containing proteins with multiple Ub-binding modules, is the primary sensor for ubiquitinated membrane proteins. Both ESCRT-I and ESCRT-II have proteins with a single Ub-binding domain and are subsequent successive recipients of the ubiquitinated cargo. ESCRT-II proteins also contain lipid-binding modules and are likely to initiate invagination of the endosomal membrane. ESCRT-III, which includes the conserved AAA+ ATPase VPS4 as a component, mediates the final abscission of the invaginated membrane to form the intraluminal vesicle. In this relay, ESCRT-I is the critical bridge between the sensor of ubiquitinated targets and the membrane-binding ESCRT-II. ESCRT-I contains three subunits that are conserved between yeast and animals, namely the inactive E2-ligase protein TSG101/VPS23, VPS28 and VPS37 (Raiborg and Stenmark, 2009). Additionally, both yeast and metazoan ESCRT-I contain a fourth subunit termed MVB12 ['multivesicular body sorting factor of 12 kD' (Chu *et al*., 2006)]; however, the MVB12 subunits from the two lineages do not show significant sequence similarity (Audhya *et al*., 2007; Chu *et al*., 2006; Konishi *et al*., 2006; Morita *et al*., 2007). Metazoan MVB12 was shown to be critical for receptor endocytosis and also virus release (Morita *et al*., 2007). Given its key role in receptor downregulation, we were interested in understanding if the lack of detectable similarity with yeast MVB12 might reflect emergence of novel adaptations in animals.

Accordingly, we analyzed the animal MVB12 proteins using sensitive sequence and structure analysis methods and identified two novel conserved domains in them. Identification of these domains allowed us to detect several putative, uncharacterized ESCRT-I subunits in animals. Characterization of these domains also provides new insights into recognition of cargo by endosomal sorting regulators.

2 METHODS

Profile searches were conducted using the PSI-BLAST program (Altschul *et al*., 1997) with a default profile inclusion expectation (E)-value threshold of 0.01. Profile–profile comparisons were performed using the HHpred program (Soding *et al*., 2005). Hidden Markov model searches were conducted using JACKHMMER from the HMMER3 package (Eddy, 2008). Multiple alignments were constructed using Kalign (Lassmann and Sonnhammer, 2005) followed by manual adjustments based on PSI-BLAST results. Protein secondary structure was predicted using a multiple alignment as the input for the JPRED program (Cuff *et al*., 1998). The 3D structures were rendered using the PYMOL program (http://www.pymol.org/).

3 RESULTS AND DISCUSSION

3.1 Identification of the UMA and MABP domains

To investigate the relationships of the animal MVB12, we used the closely related human paralogs MVB12A (FAM125A; gi: 24308440) and MVB12B (FAM125B; gi: 58761488) as seeds for sequence profile searches with the PSI-BLAST program and

iterative hidden Markov model searches with the JACKHMMER program. The N-terminal region (human MVB12A, region 1-150) and the C-terminal region (MVB12A, region 210–264) recovered distinct sets of proteins. The N-terminal region of the MVB12A/B proteins hit several proteins from eukaryotes and bacteria. These included proteins typified by DENND4A/B/C from vertebrates (iteration 2, 10^{-5} in a PSI-BLAST search), the membrane-trafficking regulator Crag from *Drosophila* (iteration 3, 10^{-19}), bacterial proteins typified by the MAC/Perforin (MACPF)-like protein plu1415 (PDB: 2QP2; iteration 4, 10^{-10}) from *Photorhabdus luminescens* and uncharacterized proteins from choanoflagellates and stramenopiles (Figs 1 and 2). In contrast, the C-terminal region produced significant hits only to metazoan proteins. These included the human ubiquitin-associated protein-1 (UBAP1; $e = 10^{-3}$, iteration 3 in PSI-BLAST), which is implicated in nasopharyngeal carcinoma risk and fronto-temporal lobar degeneration (Rollinson *et al.*, 2009; Wu *et al.*, 2009). Also recovered were several other poorly characterized proteins, including at least one orthologous group of proteins conserved in vertebrates prototyped by the human protein LOC390595 (iteration 3, 10^{-5} in PSI-BLAST searches) and another group conserved across Metazoa typified by human tcag7.903 ($e = 10^{-4}$, iteration

Only known domains are represented above, with unknown or uncharacterized regions omitted for simplicity. See text for domain name abbreviations.

6). These findings indicated that the metazoan MVB12 proteins contain two distinct conserved domains that occur independently in various proteins (Figs 1 and 2; the MVB12 orthologs are currently grouped as a single-domain model DUF2464 in the PFAM database, which does not detect the other homologous proteins identified in the current study).

Furthermore, searches with the N-terminal domain of MVB12A/B and the equivalent domain in the DENND4A/B/C and Crag indicated that it has an internal repeat structure of three homologous segments. Consistent with this, the structurally characterized representative, *Photorhabdus* plu1415, showed that this region precisely corresponds to a type-I β-prism domain with an internal 3-fold symmetry (Rosado *et al*., 2007). Each of the three subdomains of the β-prism structure is a distinctive three-stranded β-sheet (Fig. 2B) that was congruent to the repeat units detected in the sequence searches (Fig. 1B). This domain shares a triradial symmetry with β-sheets parallel to the prism axis as in the type-I β-prism domains observed in the vitelline membrane outer layer protein I (VMO-I) and the *Bacillus thuringiensis* δ-endotoxin (Shimizu and Morikawa, 1996). However, the topology of the strands in the β-sheet of the individual subdomains of the *Photorhabdus* plu1415 β-prism is entirely different (Fig. 2B). We named this novel domain the MVB12-Associated β-prism (MABP). A multiple alignment of the MABP domain showed that majority of the eukaryotic versions contains a conserved cysteine in the first and third subdomain of the β-prism (Fig. 1B). We named the C-terminal domain of MVB12A/B domain, which is shared with UBAP1 as the UBAP1-MVB12-associated (UMA) domain. A multiple alignment of the UMA domain showed a conserved proline followed by a hydrophobic residue in the N-terminus and a nearly absolutely conserved glutamate at the C-terminus (Fig. 1A). Secondary structure prediction using JPRED suggested that it adopts an $\alpha + \beta$-fold (Fig. 1A).

3.2 Domain architectures and functional interactions of MABP and UMA domain proteins

To understand the functional significance of the MABP and UMA domains, we systematically determined domain architectures of the proteins which contain them (Fig. 2A). In addition to co-occurring with the UMA domain in MVB12 proteins found in all metazoans, the MABP domain is found independently of it but fused to several other domains: (i) In a group of related proteins typified by Crag and DENND4A/B/C found in metazoans and ciliates, it is present N-terminal to the triad of domains known as uDENN, DENN and dDENN (Levivier *et al*., 2001). Additionally, C-terminal to the DENN triad, these proteins have a pentatricopeptide repeat (PPR), a novel Zn-ribbon (ZnR) and an uncharacterized α-helical domain. (ii) Two MABP domains are inserted into the choanoflagellate VPS13 ortholog, which also contains APG2-C and Dysferlin (DysF) domains. (iii) Stand-alone MABP domains are found in certain fungi. (iv) In stramenopiles, several architectures are observed including fusions to peptide-N-glycanase-type transglutaminase and PUG domains (*Phytophthora infestans* PITG_02329), to 8 EF-HANDs (EFh) and two Ub-binding ZnR domains (zUb in Fig. 2A, *P.infestans* PITG_06630) and to a Sec7 domain (*Phaeodactylum* PHATRDRAFT_49198). Two MABP domains are also found inserted into a deubiquitinating peptidase (DUB) domain in another *P.infestans* protein (PITG_02561; it also contains six N-terminal zUb Ub-binding ZnRs). (v) In bacteria, the MABP domain occurs as a solo (e.g. *Frankia* FRAAL0413), fused to the C-terminus of a MACPF domain (e.g. plu1415) or at the N-terminus of a protein with two types of β-helix repeats (bH1/2) and a novel cysteine-containing domain (CCD) that are typical of cell-wall proteins (e.g. *Clostridium* CLOL250_02048; Fig. 2A and Supplementary Material). In eukaryotes, several of the fused domains have been implicated in trafficking machinery: the DENN domain is a Rab GEF that is required for Rab35-mediated recycling of endosomal proteins and trafficking of surface proteins to the apical membrane (Allaire *et al*., 2010). VPS13 and APG2-C domains have been implicated in protein cycling through the trans-Golgi network and formation of vesicles targeted for autophagy (Rampoldi *et al*., 2001). The other fusions are to DUBs and deglycanases that are also involved in the sorting of cargo in the trafficking process (Raiborg and Stenmark, 2009; Yoshida and Tanaka, 2010). In particular, the Ub-binding ZnRs associated with the MABP domain in at least two proteins have been found to bind monoubiquitin, a key trafficking signal (Raiborg and Stenmark, 2009). MABP domain-containing *Drosophila* Crag protein localizes to endosomal vesicle and plasma membranes (Denef *et al*., 2008). Likewise, bacterial proteins with MABP-MACPF domains have been suggested to target membranes (Rosado *et al*., 2007). Vertebrate MACPF proteins contain a fusion to the lipid-binding C2 in place of the MABP domain. These contextual connections suggest that the MABP domain has a membrane-associated function, perhaps even specific interactions with membrane components. The structure of the MABP domain in plu1415 reveals several exposed hydrophobic residues that are

consistent with such an interaction. Hence, it is plausible that the eukaryotic MABP domains are adaptors that help linking other associated domains found in the same polypeptide to vesicular membranes.

In MVB12, the region including the UMA domain, but not the MABP domain, has been shown to interact with the N-terminal part of VPS37 and the C-terminal part of TSG101, both ESCRT-I components (Morita *et al*., 2007). This suggests that the UMA domain probably specifically recruits MVB12 to the ESCRT-I complex to form a quaternary complex. In UBAP1 and LOC390595, the UMA domain is fused to three C-terminal UBA domains, which are known to bind ubiquitin (Raiborg and Stenmark, 2009). Hence, they could interact via the UBA domains with ubiquitinated tails of membrane proteins, while their UMA domains recruit them to the core ESCRT-I complex. The remaining UMA domain proteins (e.g. tcag7.903 group; Fig. 2A) have their own conserved N-terminal extensions that could potentially interact with specific protein partners. Based on these observations, we propose that the different UMA domain proteins might function as alternative MVB12-like subunits that recruit different targets via their specific interaction modules (such as MABP or UBA or the specific extensions) to the ESCRT-I complex. Thus, different types of UMA domains are likely to be required for downregulation of different sets of receptors in animals.

4 GENERAL CONCLUSIONS

Identification of the MABP and UMA domains throws light on two vital aspects of vesicular trafficking. First, the MABP domain could be a common denominator in the recognition of specific membrane-associated features by a functionally diverse set of trafficking proteins in eukaryotes and bacterial proteins involved in pore formation and cell-wall interaction. The prediction that the diverse metazoan UMA domain proteins are alternative MVB12-like proteins implies that the recruitment of ESCRT-I to endosomal structures could occur via diverse mechanisms, including the possible direct recognition of membranes by the MABP domain, interaction with ubiquitinated peptides or other protein–protein interactions. This could have been a response to the vast expansion of diverse signaling receptors such as receptor tyrosine kinases, ion channels and 7TM receptors in the metazoan lineage. Intriguingly, we found that plants (e.g. *Arabidopsis* AT5G53330) have a conserved protein that has a series of C-terminal UBA domains closely related to those found in UBAP1. While we failed to find statistically significant similarity between the N-terminal region of these plant proteins and the UMA domain, they share a few tantalizing sequence patterns. It cannot be ruled out that these plant proteins contain a region remotely related to the UMA domain and perform a comparable function in relation with the ESCRT system.

While certain core components of this system (e.g. VPS4 and MIT domains of ESCRT-III) have been traced to archaea (Hobel *et al*., 2008), the MABP domain is not currently found in any archaea. Instead it is found in diverse bacteria, suggesting that the eukaryotes could have acquired it early in their evolution from a bacterial precursor. Thus, the eukaryotic vesicular trafficking system appears to have been pieced together from different components acquired from both archaeal and bacterial precursors.
